First part of this talk covers two works involving CP decomposition:

1. Fast Exact Leverage Score Sampling from Khatri-Rao Products with Applications to Tensor Decomposition. To appear at NeurIPS 2023: <https://arxiv.org/abs/2301.12584>
2. Distributed-Memory Randomized Algorithms for Sparse Tensor CP Decomposition. Under review: <https://arxiv.org/abs/2210.05105>

Second part of this talk: emerging extensions of above work to tensor-train decomposition. Collaboration w/ Guillaume Rabusseau, Beheshteh Rakhshan at U. Montreal.

# Sparse Tensor Candecomp / PARAFAC Decomposition

**Our Goal:** Compute an approximate rank- $R$  CP decomposition of an  $N$ -dimensional  $I \times \dots \times I$  sparse tensor  $\mathcal{T}$ :

Focus on large sparse tensors (mode sizes in the millions) and moderate decomposition rank  $R \approx 10^2$ . Assume  $|I_j| = I$  for all  $j$  and  $I \geq R$ .

# Alternating Least-Squares CP Decomposition

- ALS procedure: Randomly initialize factors  $U_1, \dots, U_N$ , iteratively optimize one factor at a time while keeping others constant.
- Optimal value for  $U_j$ :

$$\operatorname{argmin}_X \|AX - B\|_F$$

where

- $A = U_N \odot \dots \odot U_{j+1} \odot U_{j-1} \odot \dots \odot U_1$  is a **Khatri-Rao product**
- $B = \operatorname{mat}(\mathcal{J}, j)^\top$

## Randomized Linear Least-Squares

- Apply sketching operator  $S$  to both  $A$  and  $B$ , solve reduced problem

$$\min_{\tilde{X}} \|SA\tilde{X} - SB\|_F$$

- Want an  $(\varepsilon, \delta)$  guarantee on solution quality: with high probability  $(1 - \delta)$ ,

$$\|A\tilde{X} - B\|_F \leq (1 + \varepsilon) \min_X \|AX - B\|$$

- Osman talked about Gaussian / TensorSketch operators. Here, restrict  $S$  to be a *sampling* matrix: selects and reweights rows from  $A$  and  $B$ .

# Effect of Sampling Operator

$$\min_{U_j} \left\| \left[ \begin{array}{c} \odot U_k \\ k \neq j \end{array} \right] \cdot U_j^\top - \text{mat}(\mathcal{J}, j)^\top \right\|_F$$

$$\min_{U_2} \left\| \begin{array}{c} U_3 \\ \odot \\ U_1 \end{array} \right\| \cdot U_2^\top - \left\| \begin{array}{c} \cdot \\ \cdot \end{array} \right\|_{\text{mat}(\mathcal{J}, 2)} \right\|_F \rightarrow U_2 := \underbrace{\begin{array}{c} \cdot \\ \cdot \end{array}}_{\text{MTTKRP}} \cdot \begin{array}{c} U_3 \\ \odot \\ U_1 \end{array} \cdot G^+$$

- (SPALS, D. Cheng et al. 2016): Sample rows according to approximate *leverage score distribution* on  $A$ . Worst-case **exponential** in  $N$  to achieve  $(\varepsilon, \delta)$  guarantee.
- (CP-ARLS-LEV Larsen & Kolda 2022): Similar approximation, hybrid random-deterministic sampling strategy and practical improvements.
- (TNS-CP, Malik 2022): Samples from exact leverage distribution with **polynomial** complexity to achieve  $(\varepsilon, \delta)$  guarantee, but linear dependence on  $I$  for each sample.

## Our Contributions

Method	Round Complexity ( $\tilde{O}$ notation)
CP-ALS	$N(N + I)I^{N-1}R$
CP-ARLS-LEV (2022)	$N(R + I)R^N/(\varepsilon\delta)$
TNS-CP (2022)	$N^3IR^3/(\varepsilon\delta)$
GTNE (2022)	$N^2(N^{1.5}R^{3.5}/\varepsilon^3 + IR^2)/\varepsilon^2$
<b>STS-CP (ours, 2023)</b>	$N(NR^3 \log I + IR^2)/(\varepsilon\delta)$

- We build a data structure with runtime **logarithmic** in the height of the KRP and quadratic in  $R$  to sample from leverage scores of  $A$ .
- Yields the **STS-CP** algorithm: lower asymptotic runtime for randomized CP decomposition than recent SOTA methods (practical too!)

## Leverage Score Sampling

We will sample rows i.i.d. from  $A$  according to the *leverage score distribution* on its rows. Leverage score  $\ell_i$  of row  $i$  is

$$\ell_i = A [i, :] (A^\top A)^+ A [i, :]^\top$$

### Theorem (Leverage Score Sampling Guarantees)

Suppose  $S \in \mathbb{R}^{J \times I}$  is a leverage-score sampling matrix for  $A \in \mathbb{R}^{I \times R}$ , and define

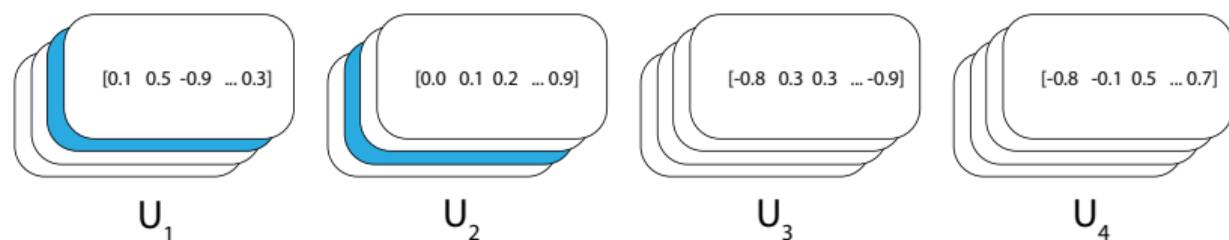

$$\tilde{X} := \arg \min_{\tilde{X}} \|SA\tilde{X} - SB\|_F$$

If  $J \gtrsim R \max(\log(R/\delta), 1/(\varepsilon\delta))$ , then with probability at least  $1 - \delta$ ,

$$\|A\tilde{X} - B\|_F \leq (1 + \varepsilon) \min_X \|AX - B\|_F$$

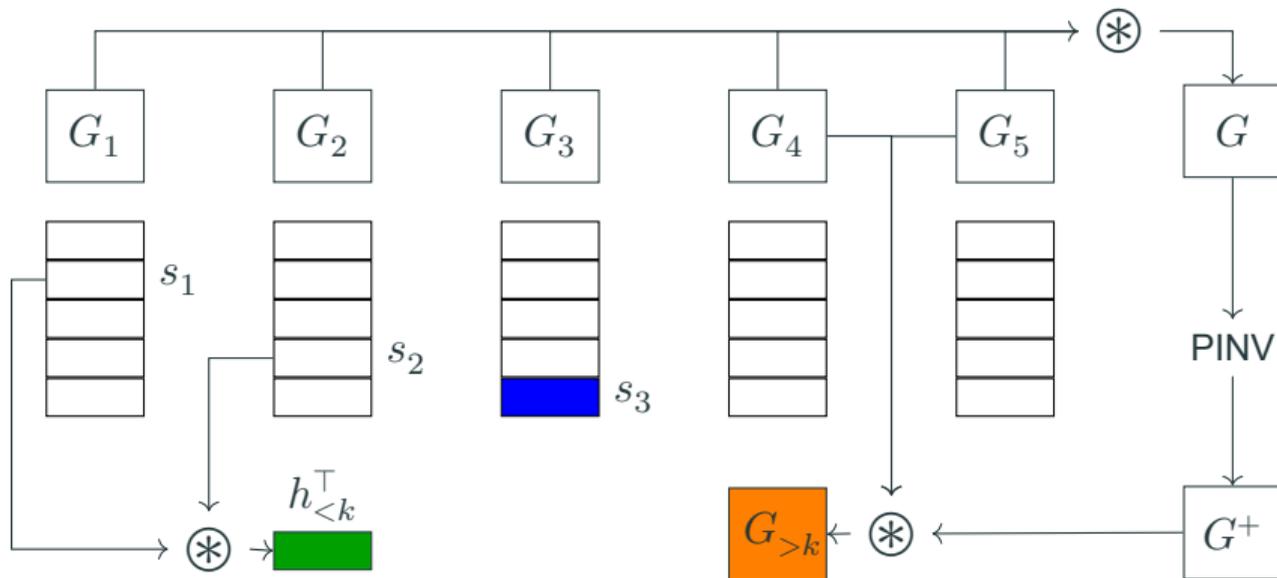

## Leverage Score Sampling

- For  $I = 10^7$ ,  $N = 3$ , matrix  $A$  has  $10^{21}$  rows. Can't even index rows with 64-bit integers.
- Instead: draw a row from each of  $U_1, \dots, U_N$ , return their Hadamard product.

- Let  $\hat{s}_j$  be a random variable for the row index drawn from  $U_j$ . Assume  $(\hat{s}_1, \dots, \hat{s}_N)$  jointly follows the leverage score distribution on  $U_1 \odot \dots \odot U_N$ .

# The Conditional Distribution of $\hat{s}_k$

## Theorem

$$p(\hat{s}_k = s_k \mid \hat{s}_{<k} = s_{<k}) \propto \langle h_{<k} h_{<k}^T, U_k[s_k, :]^T U_k[s_k, :], G_{>k} \rangle$$

## Key Sampling Primitive

$$q[i] := C^{-1} \langle h_{<k} h_{<k}^\top, U_k[i, :]^\top U_k[i, :], G_{>k} \rangle$$

- Can't compute  $q$  entirely - would cost  $O(IR^2)$  per sample per mode.
- Imagine we magically had all entries of  $q$  - how to sample? Initialize  $I$  bins,  $j$ 'th has width  $q[j]$ .
- Choose random real  $r$  in  $[0, 1]$ , find "containing bin"  $i$  such that

$$\sum_{j=0}^{i-1} q[j] < r < \sum_{j=0}^i q[j]$$

## Caching Partial Gram Matrices

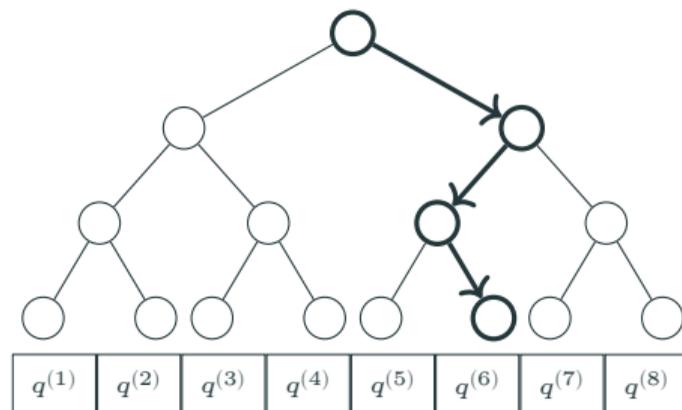

Let an internal node  $v$  correspond to an interval of rows  $[S(v) \dots E(v)]$ .

$$\begin{aligned} \sum_{j=S(v)}^{E(v)} q[j] &= \sum_{j=S(v)}^{E(v)} C^{-1} \langle h_{<k} h_{<k}^\top, U_k[j, :]^\top U_k[j, :], G_{>k} \rangle \\ &= C^{-1} \langle h_{<k} h_{<k}^\top, \sum_{j=S(v)}^{E(v)} U_k[j, :]^\top U_k[j, :], G_{>k} \rangle \tag{1} \\ &= C^{-1} \langle h_{<k} h_{<k}^\top, U_k[S(v) : E(v), :]^\top U_k[S(v) : E(v), :], G_{>k} \rangle \\ &:= C^{-1} \langle h_{<k} h_{<k}^\top, G^v, G_{>k} \rangle \end{aligned}$$

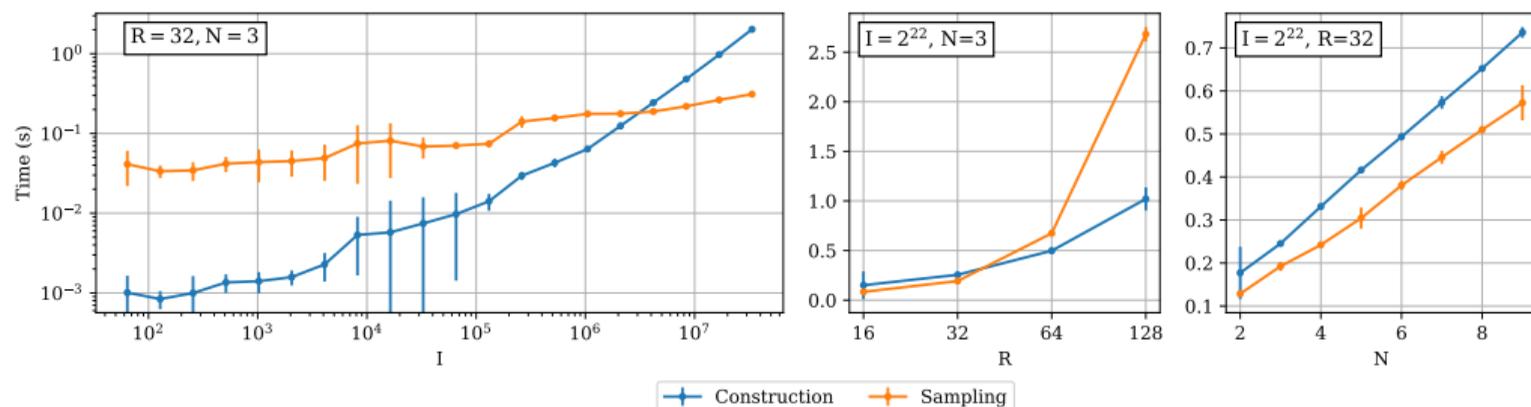

Can compute and store  $G^v$  for ALL nodes  $v$  in time  $O(IR^2)$ , storage space  $O(IR)$ .  
Only have to recompute once per ALS round.

## Efficient Sampling after Caching

- At internal nodes, compute  $C^{-1}\langle h_{<k}h_{<k}^\top, G^v, G_{>k} \rangle$  in  $O(R^2)$  time (read normalization constant from root)
- At leaves, spend  $O(R^3)$  time to compute remaining values of  $q$ . Can reduce to  $O(R^2 \log R)$ , see paper.
- Complexity per sample:  $O(NR^2 \log I)$  (summed over all tensor modes).

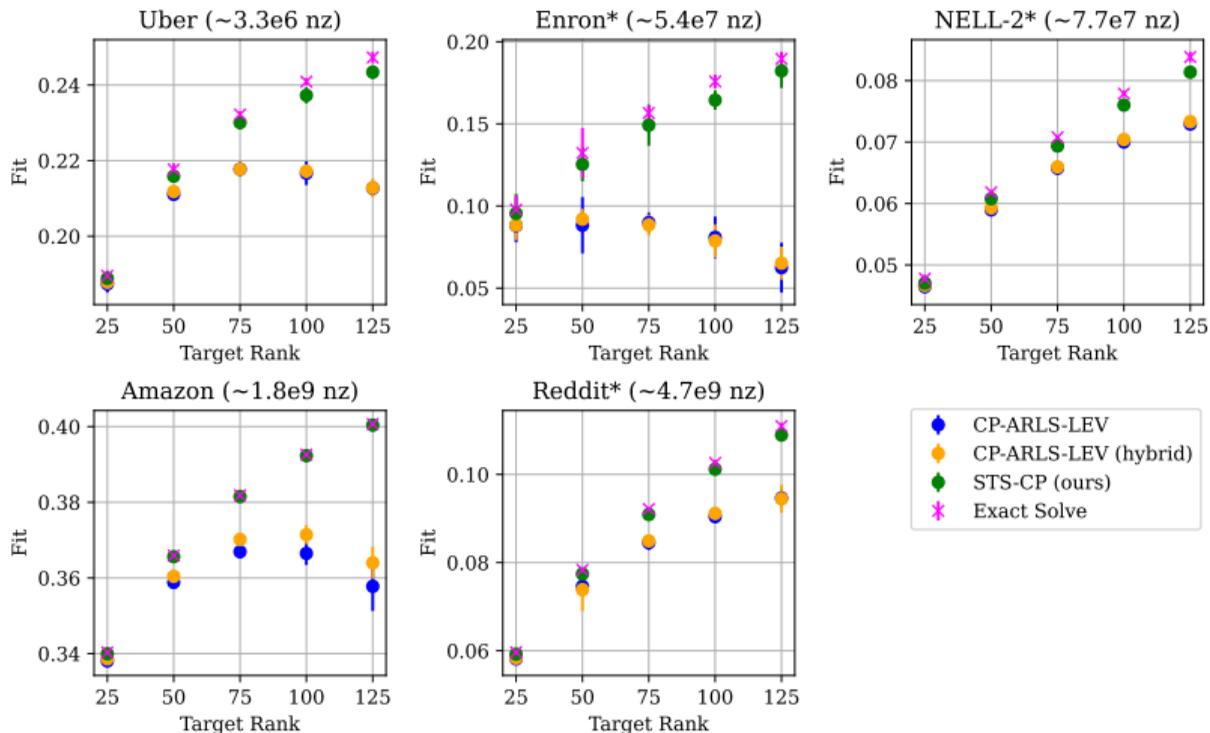

# Runtime Benchmarks (LBNL Perlmutter CPU)

C++ Implementation Linked to OpenBLAS. 1 Node, 128 OpenMP Threads, BLAS3 Construction, BLAS2 Sampling,  $J = 65,536$  samples.

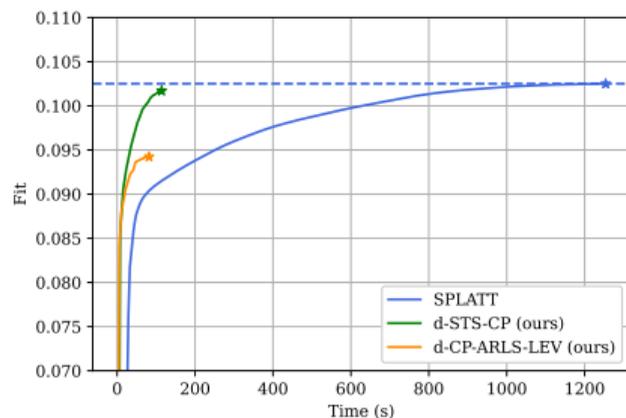

# Accuracy Comparison for Fixed Sample Count

ALS Accuracy Comparison for  $J = 2^{16}$  samples.

# Distributed-Memory High-Performance Implementation

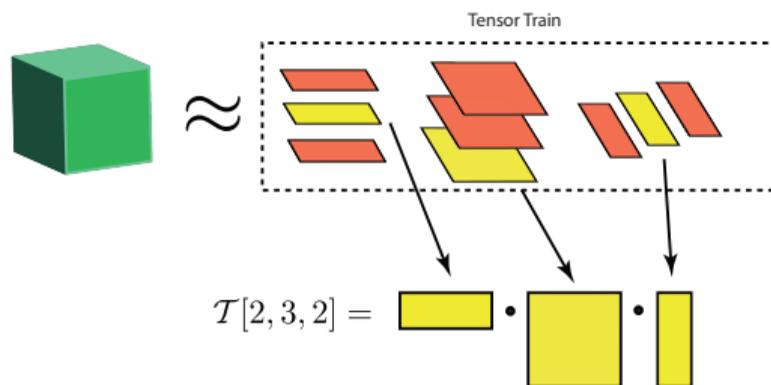

- We give high-performance implementations of STS-CP and CP-ARLS-LEV scaling to thousands of CPU cores.
- Up to 11x speedup over SPLATT
- Several communication / computation optimizations unique to randomized CP decomposition.

Accuracy vs. time, Reddit tensor,  $R = 100$ , 512 cores / 4 Perlmutter CPU nodes, 4.7 billion nonzeros.

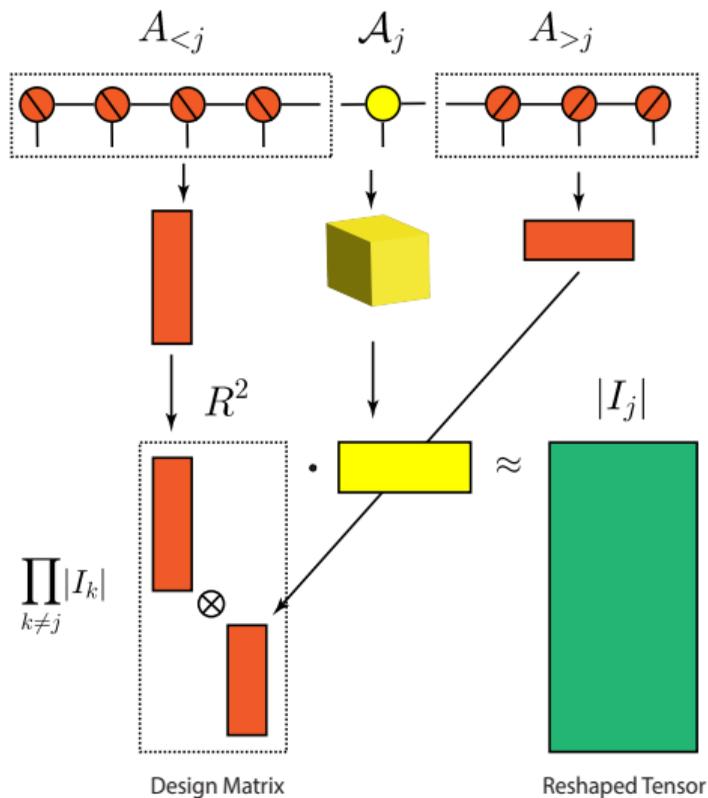

# Tensor-Train Decomposition

The tensor-train decomposition represents a tensor  $\mathcal{T}$  as a contraction between order-3 “tensor-cores”.

$j$ 'th core has dimensions  $R_j \times |I_j| \times R_{j+1}$ . Represents a tensor with  $I^N$  elements using  $O(NIR^2)$  space when all rank are equal.

# Iterative TT Optimization Problems

### Theorem (Orthonormal Subchain Leverage Sampling)

*There exists a data structure that costs  $O(IR^3)$  per tensor train core to build / update. For any  $1 < j \leq N$ , the structure can sample a row from  $A_{<j}$  proportional to its squared row norm in time*

$$O((j-1)R^2 \log I)$$

Apply same binary tree trick to the left matricizations of each core  $\mathcal{A}_j$ , exploit orthonormality to reduce complexity. Accelerates TT-ALS.

- Looking for further applications of orthonormal tensor train sketch.
- Extension to non-orthonormal case challenging, but potentially rewarding.
- If you have an application involving contraction of an unstructured operator with a tensor-train / MPS, let's talk!
